Department of Physics, Bose Institute 93/1 A. P. C Road Calcutta -700009, INDIA

We compute the *time evolving* probability of a Gaussian wave packet to be reflected from a rectangular potential barrier which is perturbed by *reducing* its height. A time interval is found during which this probability of reflection is *enhanced* (“superarrivals”) compared to the unperturbed case. Such a time evolving reflection probability implies that the effect of perturbation propagates across the wave packet *faster* than its group velocity - a curious form of “nonlocality.”

In recent years a number of interesting investigations have been reported on wave- packet dynamics in quantum-well systems [1-6]. In this paper we study the wave packet dynamics from a new perspective. The reflection/transmission probabilities for the scattering of wave packets by various obstacles are usually considered from static or unperturbed potential barriers. Generally the *time-independent* (asymptotic) values attained after a complete time evolution are calculated. Here we point out the striking effects that occur *during* the time evolution by considering dynamics of wave packet scattering from a barrier whose height is reduced to zero *well before* the asymptotic value of reflection probability is reached.

For an unperturbed barrier the reflection probability for an initially localized wave packet $\psi(x, t=0)$ is calculated by considering the wave packet as a superposition of plane waves and by writing

$$|R_0|^2 = \int |\phi(p)|^2 |R(p)|^2 dp \quad (1)$$

where $|R(p)|^2$ is the reflection probability corresponding to the plane wave component $\exp(ipx)$ and $\phi(p)$ is Fourier transform of the initial wave packet $\psi(x, t=0)$. Since a wave packet evolves in time, $|R_0|^2$ defined by Eq. (1) denotes the *time-independent* value of reflection probability pertaining to a wave packet, this value being attained in the asymptotic limit (t_∞) of the time evolution. Thus $|R_0|^2$ can be expressed in the following form

$$|R_0|^2 = \int_{-\infty}^{x'} |\psi(x, t_\infty)|^2 dx \quad (2)$$

where $\psi(x, t_\infty)$ is asymptotic form of the wave packet attained by evolving from

¹ email: dhom@boseinst.ernet.in

$\psi(x, t = 0)$ and by being scattered from a rectangular potential barrier of finite height and width. Note that x' lies at a left edge of the initial profile of the wave packet such that $\int_{-\infty}^{x'} |\psi(x, t = 0)|^2 dx$ is negligible (see Figure 1). At any instant *before* the constant value $|R_0|^2$ is attained, the time evolving reflection probability in the region $-\infty < x \leq x'$ is given by

$$|R(t)|^2 = \int_{-\infty}^{x'} |\psi(x, t)|^2 dx \quad (3)$$

Now suppose that during the time evolution of this wave packet the barrier is perturbed by *reducing* its height to zero within a very *short* but *finite* interval of time. Here by “short” time interval we mean that it is small compared to the time taken by the reflection probability to attain its asymptotic value $|R_0|^2$. We compute effects of this “sudden” perturbation on $|R(t)|^2$. The salient features of our findings are as follows:

- (a) A finite time interval is found during which $|R(t)|^2$ shows a surprising *enhancement* (we call this effect “superarrivals”) in the perturbed case even though the barrier height is reduced. This time interval and the amount of enhancement depend on the time over which the barrier height is made zero.
- (b) The way the computed reflection probability evolves implies an *incompatibility* with a form of “locality condition” which is inferred from a commonly used “particle picture” which associates the mean “velocity” of a “particle” with group velocity of the corresponding wave packet. In particular, such a “picture” is *phenomenologically* useful in the context of design and interpretation of “single particle” interference experiments using neutrons/electrons [7,8]. The type of quantum nonlocality thus exhibited involves an *action at a distance* entailing a *global* effect on the wave packet induced by a local perturbation. The resulting action propagates across the wave packet at a finite speed which is *greater* than the group velocity - a distinctly nonclassical behaviour.

In order to demonstrate the above features let us begin by writing the initial wave packet (in units of $\hbar = 1$ and $m = 1/2$, this choice of units being convenient for numerical computation) in the form

$$\psi(x, t = 0) = \frac{1}{[2\pi(\sigma_0)^2]^{1/4}} \exp \left[-\frac{(x - x_0)^2}{4\sigma_0^2} + ip_0 x \right] \quad (4)$$

which describes a packet of width σ_0 centered around $x = x_0$ with its peak moving with a group velocity $2p_0 = \frac{\langle p \rangle}{m}$ towards a rectangular potential barrier. The point x_0 is chosen such that $\psi(x, t = 0)$ has a negligible overlap with the barrier. The expectation value of energy (E) of the wave packet is given by $p_0^2 + \frac{1}{4}\sigma_0^{-2}$.

For the purpose of computing $|R(t)|^2$ given by Eq. (3) the time dependent Schrodinger equation is solved by using the numerical methods as developed by Goldberg, Schey and Schwartz [9]. In this treatment the parameters are chosen in a way ensuring the spreading of packet to be negligible during the scattering process so that it doesn't mask the effects of interest. Here we choose $x_0 = 1.2$,

$\sigma_0 = 0.05/\sqrt{2}$ and $p_0 = 50\pi$. The barrier is centered around $x_c = 1.5$ with width = 0.064. Height of the barrier (V) before perturbation is chosen to be $V = 2E$. This choice satisfies the following criteria :

(1) V is such that the reflection probability is very close to 1 since we are interested only in the reflection probability.

(2) At the same time V is chosen not to be too large. This is in order to ensure that reduction of the barrier height need not be too fast.

$|R(t)|^2$ is computed according to Eq. (3) by taking $x' = x_0 - 3\sigma_0/\sqrt{2}$. The computed evolution of $|R(t)|^2$ corresponds to the building up of reflected particles with time. More precisely, it means that a detector located within the region $-\infty < x < x'$ measures $|R(t)|^2$ by registering the reflected particles arriving in that region *up to* various instants.

First, we compute $|R(t)|^2$ for the wave packet scattered from a *static* barrier $V = 2E$. The relevant curve is shown in Figure 2 which tends towards a time-independent value which is the stationary state reflection probability $|R_0|^2$ given by Eq (2); this is numerically verified to be equivalent to the expression for $|R_0|^2$ given by Eq. (1). We then proceed to study the consequences of reducing the barrier height from $V = 2E$ to $V = 0$. The time evolution of $|R(t)|^2$ in the perturbed cases is found to show a number of interesting features.

In all the cases we study, the potential V goes to zero linearly within a *switching off time* ϵ around $t = t_p$ chosen to be 8×10^{-4} (note that numbers denoting the various instants are in terms of time steps; for example, $t = 8 \times 10^{-4}$ corresponds to 400 time steps). Here $\epsilon \ll t_0$, t_0 being the time required for $|R(t)|^2$ to attain the asymptotic value $|R_0|^2$. This short time span ϵ over which the perturbation takes place is thus given by $[t_p - \frac{\epsilon}{2}, t_p + \frac{\epsilon}{2}]$. Profile of the wave packet at $t_p = 8 \times 10^{-4}$ is shown in Figure 3. Note that at *that* instant the overlap of the wave packet with the barrier is significant.

Figure 4 shows the evolution of $|R(t)|^2$ for various values of ϵ . Different ϵ correspond to different N where N is the number of time steps involved in computing the reduction of V from $2E$ to zero, $\frac{\epsilon}{N}$ being the magnitude of each time step. Varying ϵ signifies changing the time span over which the barrier height goes to zero which in turn means different rates of reduction. We now compare the computed $|R(t)|^2$ for the particular case $N=2$ (denoted by $|R_p(t)|^2$) with that calculated for a static barrier (denoted by $|R_s(t)|^2$). This comparison is shown in Figure 5 which reveals that

$$|R_p(t)|^2 = |R_s(t)|^2 \quad t \leq t_d \quad (5)$$

$$|R_p(t)|^2 > |R_s(t)|^2 \quad t_d < t \leq t_c \quad (6)$$

$$|R_p(t)|^2 < |R_s(t)|^2 \quad t > t_c \quad (7)$$

where t_p is the instant around which the perturbation takes place, t_c is the instant when the two curves cross each other, and t_d is the time from which

the curve corresponding to the perturbed case starts *deviating* from that in the unperturbed case. Here $t_c > t_d > t_p$.

Let us now focus on a striking feature embodied in the inequality (6). As the barrier height is made zero, one does not expect at any time an increase in the reflected particle flux compared to that in the unperturbed case. Nevertheless, the inequality (6) shows that there is a finite time interval $\Delta t = [t_d, t_c]$ during which the probability of finding a reflected particle is *more* (“superarrivals”) in the perturbed case than when the barrier is left unperturbed (see Figure 5). A detector placed in the region $x < x'$ would therefore register *more* counts during this time interval Δt *even though* the barrier height had been reduced to zero prior to that. It has been checked that this effect of “superarrivals” occur for other values of N (or, ϵ) as well; see Figure 4.

Figure 4 also reveals that the probability of “superarrivals” (i.e., *the enhancement* of reflection probability) depends on N (or, ϵ). The maximum enhancement takes place for $N = 2$ and the amount of enhancement decreases with increasing N . But interestingly there is no appreciable change in the magnitude of the time interval Δt over which this enhancement occurs. In order to have a *quantitative* measure of “superarrivals” we define the parameter η given by

$$\eta = \frac{I_p - I_s}{I_s} \quad (8)$$

where the quantities I_p and I_s are defined with respect to Δt during which “superarrivals” occur

$$I_p = \int_{\Delta t} |R_p(t)|^2 dt \quad (9)$$

$$I_s = \int_{\Delta t} |R_s(t)|^2 dt \quad (10)$$

The relevant numerical results are displayed in Table 1 and variation of η with N (or, ϵ) for different cases of perturbation are shown in Figure 6. These results are summarised below:

- (a) There exists a *finite* time interval Δt during which an *increase* in the reflection probability (“superarrivals”) occurs for the perturbed cases relative to the unperturbed situation.
- (b) The time interval Δt over which this probability enhancement takes place is *not* sensitive to the span of the *switching off time* ϵ within which the barrier height is reduced to zero.
- (c) Magnitude of this probability enhancement falls off *linearly* with increasing ϵ .

We also note that both Δt and “superarrivals” given by η depend on the *instant* t_p around which the barrier is switched off. Hence *choice* of this instant for demonstrating the above effects needs to be appropriate. From the profiles of wave packet corresponding to different times of perturbation t_p (as shown in

Figure 6) it is seen that “superarrivals” is appreciable in cases where the wave packet has some significant overlap with the barrier *during* its switching off. What *optimal* condition determining the choice of t_p maximises “superarrivals” needs to be clarified. In particular, there could be choice(s) of t_p for which “superarrivals” is more than what is obtained in the present work. Further, it should be interesting to investigate whether any *lower bound* of t_p exists prior to which switching off the barrier does not give rise to “superarrivals”.

Quantum Nonlocality.- We now proceed to discuss in what sense the computed time development of $|R(t)|^2$ in the perturbed cases mentioned above entail an *incompatibility* with a certain form of locality condition. This locality condition is formulated in terms of a “particle picture” which is commonly used in interpreting wave packet behaviour. In particular, such a “picture” is phenomenologically motivated, being used in analyzing the results of neutron/electron interferometric experiments [7,8] performed in the region of so-called “self interference” where only one “particle” is required to be present inside the device at a time. In order to ensure this condition it is necessary to associate a mean “velocity” with an individual neutron/electron so that the time it stays inside the interferometer can be calculated and hence suitably adjusted by varying the relevant parameters (such as the rate of emission from a source).

A crucial point is that this mean “velocity” is assumed to be the group velocity (v_g) of the wave packet associated with the particle [10]. The average time of transit ΔT of a neutron/electron inside the device is then estimated by using the relation $\Delta T = L/v_g$ where L is the distance travelled within the device. Such a relation characterizes the type of “particle picture” which constitutes a crucial ingredient in designing and interpreting the neutron/electron self interference experiments. This “particle picture”, if applied in the specific context of the example discussed in the present paper, leads to the following Propositions.

Proposition 1: If a particle is detected at time t , it is inferred to be reflected from the barrier at an *earlier instant* $t - \frac{D}{v_g}$ where D is the separation between the detector and the barrier.

Proposition 2: Locally perturbing a barrier has *no* effect on those particles *already* reflected from the barrier.

Note that Proposition 2 is some form of *locality condition* which assumes that detection probability of the particles reflected from the barrier prior to its perturbation does *not* bear any signature of the perturbation. On the basis of the above Propositions we now proceed to derive the following constraint condition.

In our computed cases the relevant perturbation (i.e., reduction of the barrier height) commences from the instant $t_p - \frac{\epsilon}{2}$. From Proposition 1 it follows that particles reflected from the barrier *until* this particular instant are registered at a detector (placed at a distance D) *up to* an instant τ which is given by $\tau = (t_p - \frac{\epsilon}{2}) + \frac{D}{v_g}$. The locality condition (Proposition 2) therefore requires that the measured particle statistics at this detector should *not* be affected by perturbation of the barrier until the instant τ . This means that the time evolving reflection probability $|R_p(t)|^2$ in the perturbed cases is permitted by this locality condition to deviate from the reflection probability $|R_s(t)|^2$ in the static case *only after* the instant τ . In other words, if $|R_p(t)|^2$ and $|R_s(t)|^2$

are found to differ from the instant t_d , the locality condition in the form of Proposition 2 requires

$$t_d > \tau \quad (11)$$

However, the results of our computations of $|R_p(t)|^2$ and $|R_s(t)|^2$ indicate a rather strong violation of the inequality (10). Choosing $D = 0.375, v = 2p_0 = 100\pi$ and $t_p = 8 \times 10^{-4}$, the results of our calculation are displayed in Table 2.

Comparing the values of τ with those of t_d as shown in Table 2 we find that $t_d < \tau$ for all values of ϵ . A clear violation of the locality condition (10) is thus demonstrated. This form of quantum nonlocality is quite distinct from the usual nonlocality [10] which is inferred from many particle entangled states. We now elaborate a bit on the significance of this new form of quantum nonlocality.

What our computed results show is that a local change in potential (in our specific case, a reduction of the barrier height) affects a wave packet *globally*, the global effect being manifested through time evolution of the packet. The action due to local perturbation propagates across the wave packet at a finite speed say, v_e affecting the time evolving reflection probability which can be measured at different points. Thus a distant observer who records the growth of reflection probability becomes aware of perturbation of the barrier (occurring around an instant t_p) from the instant t_d when the time varying reflection probability starts *deviating* from that measured in the unperturbed case. Then v_e is given by

$$v_e = \frac{D}{t_d - (t_p - \frac{\epsilon}{2})} \quad (12)$$

From Eq. (12) it follows that the violation of locality condition (10) implies

$$v_e > v_g \quad (13)$$

i.e., the effect caused by reducing the barrier height travels across the wave packet at a speed *exceeding* the packet's group velocity. This is an intrinsically *nonclassical* "action at a distance" which is manifested even when spreading of the wave packet is ensured to be negligibly *small*.

In general, v_e depends on D, t_p, t_d , and ϵ . However, t_d is essentially determined by ϵ for a given t_p . Hence for fixed values of D and t_p , v_e depends only on ϵ . For a particular choice of $D = 0.343$ and $t_p = 8 \times 10^{-4}$, Table 3 indicates the way calculated values of v_e vary with ϵ ; the corresponding variation of the ratio of v_e with v_g is also shown in Table 3. Of course, more detailed studies are called for in order to have a precise quantitative idea about the dependence of v_e on the relevant parameters.

An important point to note from Table 3 is that v_e can exceed v_g *substantially*. It should therefore be interesting to investigate whether any *bound* exists on the ratio of v_e with v_g . It may also be worthwhile to compute our example for various cases by varying mass and width of the wave packet to see what happens to this ratio in the various limiting situations such as for large mass (classical limit) and for broad wave packets (plane wave limit).

To sum up, our work serves to reveal that much interesting and counterintuitive physics is concealed *within* the time evolution of reflection/transmission

probability for a wave packet scattered from a perturbed barrier. This has so far remained unexplored because attention is usually focused *only* on the final time independent values of reflection/transmission probability. In particular, the effects uncovered in this paper involve an intriguing interplay between “particle” and “wave” aspects of a wave packet, its conceptual ramifications warranting further probing. Such effects could also be amenable to experimental verification using the available neutron/electron “single particle” experimental arrangements [7,8].
